Quantum channel capacities - multiparty communication

Maciej Demianowicz* and Paweł Horodecki†
Faculty of Applied Physics and Mathematics
Gdańsk University of Technology, 80–952 Gdańsk, Poland

We analyze different aspects of multiparty communication over quantum memoryless channels and generalize some of key results known from bipartite channels to that of multiparty scenario. In particular, we introduce multiparty versions of minimal subspace transmission fidelity and entanglement transmission fidelity. We also provide alternative, local, versions of fidelities and show their equivalence to the global ones in context of capacity regions defined. The equivalence of two different capacity notions with respect to two types of the fidelities is proven. In analogy to bipartite case it is shown, via sufficiency of isometric encoding theorem, that additional classical forward side channel does not increase capacity region of any quantum channel with \( k \) senders and \( m \) receivers which represents a compact unit of general quantum networks theory. The result proves that recently provided capacity region of multiple access channel ([M. Horodecki et al., Nature 436 673 (2005)], [J.Yard et al., quant-ph/0501045]) is optimal also in the scenario of additional support of forward classical communication.

I. INTRODUCTION

Theory of quantum channels is nowadays very important domain of quantum information theory. The case of one sender and one receiver has been analyzed extensively. For noiseless channel the coding theorem has been established in [1,2]. The problem of noisy channels has been defined [3] on the basis where minimal fidelity subspace transmission has been defined. The alternative definition of channel transmission based on quantum entanglement has been introduced in [4] and shown [5] to coincide with that of [3]. Moreover it has been shown that forward classical communication from sender to the receiver does not help [5]. The research towards channel capacity formula [6], [7] has been finalized by asymptotic coherent information formula in two ways: there was a proof through conjectured hashing inequality [8] that has been proven [9] and a direct proof [10]. The summary of the state of the art of bipartite zero (one)–way quantum channel capacity can be found in [11]. Further other capacity notions measuring the ability to transmit classical information via quantum channel [12] or its entanglement assisted analog [13] have been analyzed. The first notion leads to well known additivity conjecture (see [14]) liking four conjectured relations form quantum information theory. In a mean time much more has been known about relations between different versions of channel capacities [15] (see [16], [17], [18]).

Some time ago quantum channels with more than one sender/receiver have attracted more attention. Sending classical information via multiple access quantum channel has been considered first in [19]. The issue of sending quantum information in general multiparty scenario has been raised in [20] where in particular it has been shown that quantum broadcast channel capacity with two-way classical communication is nonadditive. This is linked to superactivation of multipartite bound entanglement phenomenon [21]. Recently the capacity region for multiple access channel have been provided via quantum-state merging technique [22], [23] and direct technique using some links between classical-quantum and quantum-quantum transfer [24].

Here we consider most general scenario like in [21] and generalize most important results from bipartite case. We achieve it by developing alternative (local) versions of quantum fidelities and then adopting with some refinements and modifications techniques form Refs. [5] and [8]. In particular, we consider two versions of quantum information transfer: minimal subspace fidelity [5] and entanglement fidelity from Ref. [8]. We generalize the result of the latter showing that the capacity regions defined with respect to both fidelities coincide under so-called QAEF assumption about the ensembles describing local senders. We also show that if one drops the latter assumption then quantum capacity regions of multiple access channel and \( k \)-user channel do not change if one removes encodings which generalizes results of [8].

Finally we generalize one of the results of [5] showing that in general case of \( k \) senders and \( m \) receivers forward classical communication does not improve capacity regions. This result in particular implies that the regions derived in [22], [24] do not change if we allow the senders to be supported by one-way classical channel.

The paper is organized as follows. In section II we recall two definitions of bipartite channel capacities. Then we turn to multiparty case and introduce two types of fidelities, and define the corresponding capacities regions. We also provide alternative (local) versions of the fidelities and show their equivalence to the previous ones. In section III we show that the capacity defined under minimal subspace transmission is equivalent to that defined

*Electronic address: maciej@mif.pg.gda.pl
†Electronic address: pawel@mif.pg.gda.pl
by entanglement transmission fidelity under assumption of QAEP of the sources. In section IV we prove, using in particular local versions of the fidelities, that encoding in zero-way regime can be always replaced with partial isometry encoding and by its trace–preserving extension. We consider independently special cases of $k$-users and multiple access channels and show that entanglement transmission capacity regions do not change if we abandon encoding operations. In section V we show one of the central results of the paper i.e. that forward classical communication does not change the capacity regions for general $km$-user channel when one can have in general full case of $km$ quantum information „flows” (this is if any of $k$ senders wants to send quantum information to all the $m$ receivers). The chapter VI contains the discussion and conclusions.

II. PRELIMINARIES

A completely positive operation which is trace–preserving is called a quantum channel. We will analyze situation in which one group of parties want to send information to the other, or two–way when classical messages fly in both directions. We use following symbols respectively the other, or two–way when classical messages fly in communication when no information is exchanged, one–way encoding and set dim $H^{\otimes n}$ of an article we will call this maps encoding and decoding.

Remark on notation; Logarithms are taken to basis 2. We use $\Psi$ to denote projector $|\Psi\rangle\langle\Psi|$.

A. Protocols

Let $C$ denote classical information exchanged between two groups of parties. We say about zero–way communication when no information is exchanged, one–way forward or backward if only one group communicates the other, or two–way when classical messages fly in both directions. We use following symbols respectively $C = \emptyset, \rightarrow, \leftarrow, \leftrightarrow$ in these cases. Let $A = \{A_i\}_{i=1}^k = \{\{A_i^1\}_{i=1}^k\}_{i=1}^l$, $B = \{B_i\}_{i=1}^m = \{\{B_i^1\}_{i=1}^m\}_{i=1}^l$ denote parties taking part in communication (we have $k$ senders each holding $l_i$ particles and $m$ receivers each getting $b_i$ particles; of course number of particles on both sides is the same) and $H_A = \otimes_{i=1}^k H_{A_i} = \otimes_{i=1}^l \otimes_{a=1}^{l_i} H_{A_i}^a$, $H_B = \otimes_{i=1}^m H_{B_i} = \otimes_{i=1}^l \otimes_{b=1}^{b_i} H_{B_i}^b$ Hilbert spaces associated to their particles. Let $\varepsilon(n)$ and $D(n)$ be trace–nonincreasing maps acting as follows $\varepsilon(n) : B(H_A^{\otimes n}) \rightarrow B(H_A^{\otimes n})$ and $D(n) : B(H_A^{\otimes n}) \rightarrow B(H_B^{\otimes n})$, where “$i/o Ch$” stands for the input/output channel (in further part of an article we will call this maps encoding and decoding and set dim $H_A = \dim H_B$). We will call a quantum protocol (shortly protocol) $P^C$ supplemented by classical side information $C$ a set of maps $\{P^C_n\}$ mapping channels $\Lambda^{\otimes n} : B(H_A^{\otimes n}) \rightarrow B(H_B^{\otimes n})$ into channels $\hat{\Lambda}(n) : B(H_A^{\otimes n}) \rightarrow B(H_B^{\otimes n})$. Due to the different usage of classical information we have different forms of the maps. That is, in case of $C = \emptyset$ we have

$$P^C_n(\Lambda^{\otimes n}) = D(n)\Lambda^{\otimes n}\varepsilon(n),$$

for $C = \rightarrow$ the map is

$$P^C_n(\Lambda^{\otimes n}) = \sum_{j} D_j^{(n)}\Lambda^{\otimes n}\varepsilon_j^{(n)},$$

where $D_j^{(n)}$ and $\varepsilon_j^{(n)}$ operate on the same spaces as $D(n)$ and $\varepsilon(n)$ and $\sum_{j} \varepsilon_j^{(n)} = \varepsilon(n)$. The most sophisticated case is the two–way communication scenario $C = \leftarrow \leftrightarrow$ (sometimes called ping–pong protocol) $25$. Both groups of parties, $A$ and $B$, perform POVM-s in turn where any particular POVM can depend on all of the results obtained in previous ones. This corresponds to sequence of families of operations $V_{k_1}, V_{k_2}, ..., V_{k_l}$ with trace preservation condition $\sum_{k_1} \sum_{k_2} \sum_{k_l} V_{k_1}^{l_1} V_{k_2}^{l_2} ... V_{k_l}^{l_l} = I$ for all $l$. Thus, denoting $k = \{k_1, k_2, ..., k_l\}$, we have

$$P^C_n(\Lambda^{\otimes n}) = \sum_{k} B_{A_k^{(n)}} A_{A_k^{(n)}}^{(n)} \Lambda^{\otimes n} A_{A_k^{(n)}}^{(n)},$$

where $A_{A_k^{(n)}}$ and $B_{A_k^{(n)}}$ act on the same spaces as $\varepsilon(n)$ and $D(n)$ respectively.

One can show that the latter is the most general form of LOCC including previous ones. However for the sake of further convenience we treated these cases separately.

B. Quantum channel rates, fidelities, and capacities (single user case)

There are various notions of quantum capacity rates and transmissions (see e.g. $12$). Here we shall recall two ones that historically played the most important role.

1. Subspace transmission

We start with the concept of subspace transmission which was introduced by Bennett et al.$2$.

The idea is to send pure states from the Hilbert space $H$ being the subspace of a channel input Hilbert space $H_i Ch$ with pure state fidelity defined as

$$F_s(H, \Lambda) = \min_{|\psi\rangle \in H} \langle \psi|\Lambda(\psi)|\psi\rangle (4)$$

We define a rate of such transmission with a protocol $P^C$ as

$$R_s(P^C, \Lambda) = \lim_{n \rightarrow \infty} \frac{\log \dim H^{(n)}}{n}$$

where $|a, b\rangle = \frac{1}{\sqrt{2}}(|a\rangle + |b\rangle)$.
and say that is achievable if for a given protocol we have pure state fidelity tending to one in the limit of large \( n \), i.e.

\[
F_s \left( \mathcal{H}(n), \mathcal{P}_n, \Lambda^\otimes n \right) \xrightarrow{n \to \infty} 1.
\]  

(6)

We will say that in this case protocol is reliable. It is important to note that here we consider only the protocols for which the limit exists (in contrast to the original version where \( \text{limit sup} \) was put in this place), but it can easily be shown not to be a restriction. Quantum channel capacity for subspace transmission is defined as the supremum of all achievable rates produced by all considered protocols \( \mathcal{P}_C \). We use \( Q_{s}^{C} \) to denote capacity in this case

\[
Q_{s}^{C} (\Lambda) = \sup_{\mathcal{P}_C} R_s(\mathcal{P}_C, \Lambda).
\]  

(7)

There is also an alternative way to cope with the problem of quantum information transmission - entanglement transmission.

2. Entanglement transmission

The idea of entanglement transmission was developed in \( \mathcal{F} \) and is as follows. Alicia produces bipartite state \( \Psi_{AB} \) and sends its subsystem \( B \) down the channel \( \Lambda \) to Bob. The quantity which measures the resemblance of the output bipartite state to the initial \( \Psi_{AB} \) is called entanglement fidelity and is defined by the relation (we use here notation staying in agreement with one used in \( \mathcal{F} \))

\[
F_e(\Psi_{AB}, \Lambda) = \langle \Psi_{AB} | k^A \otimes \Lambda (\Psi_{AB}) | \Psi_{AB} \rangle.
\]  

(8)

It can be shown that it depends on \( \Psi_{AB} \) only through \( \varrho_B \) and \( \Lambda \). The entanglement transmission rate in the given protocol \( \mathcal{P}_C \) for the source \( \varrho^{(n)} \) can be defined formally as

\[
R_e(\mathcal{P}_C, \Lambda) = \lim_{n \to \infty} \frac{S(\varrho^{(n)})}{n}.
\]  

(9)

Here \( \varrho^{(n)} \) is a reduced Alicia’s block density matrix corresponding to bipartite pure state \( \Psi^{(n)}_{AB} \), part of which is transmitted down the new channel \( \mathcal{P}^E_C \) (\( \Lambda^\otimes n \)) that involves both encoding and decoding procedures.

As previously we say that the rate is achievable if

\[
F_e \left( \Psi^{(n)}_{AB}, \mathcal{P}^E_C, \Lambda^\otimes n \right) \xrightarrow{n \to \infty} 1.
\]  

(10)

Channel capacity is defined analogously to the previous case as

\[
Q_{e}^{C} (\Lambda) = \sup_{\mathcal{P}_C} R_e(\mathcal{P}_C, \Lambda).
\]  

(11)

Barnum et al. \( \mathcal{F} \) have shown that both definitions coincide and give the same number for sources which satisfy quantum asymptotic equipartition property (QAEP) i.e. for all \( \varrho^{(n)} \) that have asymptotically uniform spectrum in a special sense (see Appendix).

Recently it has also been shown \( \mathcal{F} \) that it is equal to the so-called coherent information rate.

C. Quantum channel rates, fidelities, and capacities (multiuser case)

Let us now turn to the multiuser case and consider MAC, BC, and km–UC.

We then have in the case of subspace transmission in most general case of km–UC.

\[
F_e \left( \otimes_{j=1}^{k} \left( \otimes_{\alpha=1}^{l_j} \mathcal{H}^\alpha_j \right), \Lambda \right) = \min_{\otimes_{\alpha=1}^{l_j} \mathcal{H}^\alpha_j} \left( \otimes_{j=1}^{k} \left( \otimes_{\alpha=1}^{l_j} | \psi^\alpha_j \rangle \right) \Lambda \left( \otimes_{j=1}^{k} \left( \otimes_{\alpha=1}^{l_j} | \psi^\alpha_j \rangle \right) \right) \right)
\]  

(12)

and in case of entanglement transmission

\[
F_e \left( \otimes_{j=1}^{k} \left( \otimes_{i=1}^{l_j} | \psi_{i(AB)}^j \rangle \right), \Lambda \right) = \left( \otimes_{j=1}^{k} \left( \otimes_{i=1}^{l_j} | \psi_{i(AB)}^j \rangle \right) \right)
\]  

(13)

We will use the term global fidelities to name above quantities. In each scenario we can assign every \( i \)-th transmission between \( i \)-th (sub)sender (sender sending one of her subsystem) and proper receiver in a manner we have done in the single user case. Literally, we define the rates as (we shall abbreviate notation here)

\[
R^{(i)}_{s} = \lim_{n \to \infty} \frac{\log \dim \mathcal{H}_{i}^{(n)}}{n}
\]  

(14)

for subspace transmission, where \( \mathcal{H}_{i}^{(n)} \) is the subspace of \( i \)-th input Hilbert space \( \mathcal{H}_{i(AB)}^{(n)} \), and for entanglement transmission

\[
R^{(i)}_{e} = \lim_{n \to \infty} \frac{S(\varrho_{i}^{(n)})}{n},
\]  

(15)

where \( \varrho_{i}^{(n)} \) can be represented as a quantum material produced by \( i \)-th source \( \Sigma^{(i)} \) but formally is just a (Alicia’s) reduced state of the bipartite pure state \( \Psi_{i(AB)}^{(n)} \).

Similarly to the single user case we say that the rates are achievable if there exists protocol for the given type of the scenario (i.e. for instance it requires product encoding but joint decoding in case of multiply access channel) such that senders can reliably, i.e. with global fidelity corresponding to those rates approaching one, send information to the side of receivers. Formally we require (following \( \mathcal{F} \)) the global fidelity to approach unity, but it can be easily seen that this is equivalent to the same requirement for set of local fidelities (see next subsection).

We define quantum channel capacity to be a set of all \( L \)-tuples \( (L = \sum_{i=1}^{k} l_i) \) of achievable rates
[R^{(1)}, R^{(2)}, ..., R^{(L)}]. Here they will be one of three types: (i) from \(k\) senders to one receiver in case of MAC (ii) from \(k\) senders to \(m\) receivers in case of \(km\)-UC and (iii) from single sender to \(k\) receivers in case of BC.

Other capacities will be analyzed in detail elsewhere [26].

D. Alternative expressions for fidelities

Instead of global fidelities, expressing resemblance of the whole state on input to the whole state on the output, we can introduce local fidelities measuring how each density matrix sent through the channel was affected by its action. Namely we have for subspace and entanglement transmission respectively

\[
F^{(j,i)}_{s}(H_{j}^{i}, A) = \min_{\psi_{j}^{i}\in\mathcal{S}_{a_{i}=1}} \langle \psi_{j}^{i} | \text{tr}_{AB} \rho_{j}^{i} A (\otimes_{j=1}^{i} \rho_{a_{i}=1}^{0} \psi_{j}^{0}) | \psi_{j}^{i} \rangle,
\]

\[
F^{(j,i)}_{e}(\Psi_{AB}^{j}, A) = \langle \Psi_{AB}^{j} | \text{tr}_{AB} \lambda_{j}^{i} A (\otimes_{j=1}^{i} \lambda_{a_{i}=1}^{0} \Psi_{AB}^{0}) | \Psi_{AB}^{i} \rangle.
\]

Following lemmas show that we can freely switch from global to local fidelities (and the opposite way) as they both coincide in case of high limit.

Lemma 1 For any \(k\)-partite density matrix \(\rho_{k}\) and arbitrary states \(\phi_{1}\) satisfying \(\langle \otimes_{i=1}^{k} \phi_{1} | \otimes_{i=1}^{k} \phi_{1} \rangle > 1 - \epsilon\) we have (i) for all \(i\) \(\langle \phi_{1} | \rho_{j}^{i} | \phi_{1} \rangle > 1 - \epsilon\) and (ii) \(\langle \otimes_{i=1}^{k} \phi_{1} | \otimes_{i=1}^{k} \rho_{j}^{i} | \otimes_{i=1}^{k} \phi_{1} \rangle > 1 - k\epsilon.

Proof: Proof is straightforward. Consider property (i). For \(k=2\) we prove it by writing partial trace over subsystem 1 in the bases \(|\phi_{1}^{j}\rangle\) (with \(j\) enumerating the basis vectors) and by taking \(|\phi_{1}^{0}\rangle = |\phi_{1}\rangle\) and considering respective fidelity. We then have

\[
\langle \phi_{2} | \text{tr}_{1} \rho_{12} | \phi_{2} \rangle = \sum_{j \neq 0} \langle \phi_{j}^{1} | \otimes \langle \phi_{2} | \rho_{12} | \phi_{1}^{j} \otimes | \phi_{2} \rangle + \langle \phi_{1} \otimes \langle \phi_{2} | \rho_{12} | \phi_{1} \rangle \otimes | \phi_{2} \rangle.
\]

which immediately gives the desired bound because of the positivity of the first term and the assumption.

For any \(k > 2\) the proof goes in the same way, only instead of subsystem 2 we consider all the other subsystems. This gives property (i) for index \(i = 1\). By permutation we get the same for all other indices.

Let us pass to the property (ii). It immediately follows by multiplication of inequalities from (i) and the fact that \((1-\epsilon)^{k} \geq 1 - k\epsilon\) which easily can be proven by induction.

Lemma 2 For any \(k\)-partite density matrix \(\rho_{k}\) and arbitrary states \(\phi_{1}\) satisfying \(\langle \otimes_{i=1}^{k} \phi_{1} | \otimes_{i=1}^{k} \phi_{1} \rangle > 1 - \epsilon_{1}\) we have \(\langle \otimes_{i=1}^{k} \phi_{1} | \otimes_{i=1}^{k} \rho_{k} | \otimes_{i=1}^{k} \phi_{1} \rangle > 1 - k\epsilon_{1}\).

Proof. - Again here it is enough to prove the observation for \(k = 2\) since for higher \(k\) the induction method does the job.

As before we introduce orthonormal bases \(|\phi_{1}^{j}\rangle, |\phi_{2}^{j}\rangle\). Let us now define \(\rho_{op,rs} = \langle \phi_{1}^{0} | \otimes \langle \phi_{2}^{0} | \rho_{12} | \phi_{1}^{j} \rangle \otimes | \phi_{2}^{j} \rangle\). Then we have (because of unit trace of \(\rho_{12}\))

\[
\sum_{i \neq 0} \rho_{i0,00} + \sum_{j \neq 0} \rho_{0j,00} + \sum_{i \neq 0, j \neq 0} \rho_{ij,ij} = 1.
\]

On the other hand the condition \(\langle \phi_{1} | \rho_{1} | \phi_{1} \rangle > 1 - \epsilon_{1}\) takes the form

\[
\sum_{i \neq 0} \rho_{i0,00} + \sum_{j \neq 0} \rho_{0j,00} > 1 - \epsilon_{1}
\]

which, if put into the previous inequality, gives \(\sum_{i \neq 0} \rho_{i0,00} + \sum_{i \neq 0, j \neq 0} \rho_{ij,ij} < \epsilon_{1}\) which implies also \(\sum_{i \neq 0} \theta_{i0,00} < \epsilon_{1}\). The latter put into the condition \(\langle \phi_{2} | \rho_{12} | \phi_{2} \rangle > 1 - \epsilon_{2}\) rewritten as \(\sum_{i \neq 0} \rho_{i0,00} > 1 - \epsilon_{2}\) leads to \(\theta_{00,00} > 1 - \epsilon_{1} - \epsilon_{2}\) which concludes the desired proof for \(k = 2\). As mentioned, for higher \(k\) the proof goes by induction.

Application of the above lemmas to fidelities is obvious, as we can combine both lemmas to get "if and only if" statement: Global fidelities are high iff local ones are so.

III. ENTANGLEMENT AND SUBSPACE TRANSMISSION: AN EQUIVALENCE

In this section we argue that quantum capacity of a quantum channel for entanglement transmission is equal...
to that of subspace transmission in multiuser communication scenarios for sources satisfying QAEP. What is
worth to be stressed equivalence holds for every type of the protocol involved i.e. every type of classical side
information. This due to the fact that the proof does not specify protocol.

1. Subspace transmission follows from entanglement transmission

We employ techniques used in 5 and use results of section IID. Assume each of k senders’ every \( g_l^{(n)} \)
(shortly \( g_l^{(n)} \)) satisfy QAEP and can be sent reliably (i.e. with high local entanglement fidelity, consequently
global). As noted in 5 we can then restrict ourselves to \( g_l^{(n)} \) projected onto its typical subspace. We use
this fact and assume that this restricted source is sent with local entanglement fidelity at least \( 1 - \eta \) (by
the lemma 2 global entanglement fidelity is at least \( 1 - \sum_{l=1}^{L} \eta, \ L = \sum_{i=1}^{k} l_i \)). We recursively remove
the lowest pure–state fidelity vectors \( |\phi_l^{(n)}(g_l^{(n)}) \rangle \) (consequently dimensions) from the \( K_l \)-dimensional support of each \( g_l^{(n)} \) in such a manner that for each \( m \) we keep an operator \( g_l^{(n)} - \sum_{i=1}^{m} q_i |\phi_l^{(n)}(i)|\rangle \langle \phi_l^{(n)}(i) | \) positive (consequently a tensor product of them). We then have \( g_l^{(n)} = \sum_{i=1}^{K_l} q_i |\phi_l^{(n)}(i)|\rangle \langle \phi_l^{(n)}(i) | \), which means that \( \{ q_i, |\phi_l^{(n)}(i) \rangle \} \)
constitute a pure–state ensemble for \( g_l^{(n)} \). After our removal procedure we are left (for every \( g_l^{(n)} \))
with a subspace with dimension \( D_l = K_l - n_l \), where \( n_l \) is the number of removed dimensions, from
which each state has pure–state fidelity

\[
F^{(l)} = 1 - \frac{1}{\prod_{p=1}^{L} \alpha_p},
\]

(\( \alpha_p \equiv \sum_{i=1}^{n_p} q_i^2 \)). We also get the bound for the dimension of the remaining subspaces. Namely
\( D_l \geq (1 - \alpha_l)2^{n_l(S_l - \epsilon_l)} \), which gives the rate for subspace transmission
\( \log D_l \geq \log (1 - \alpha_l) + S_l(S_l - \epsilon_l) \). The latter means that all rates for subspace transmission at least as large
as for entanglement transmission are achievable.

2. Entanglement transmission follows from subspace transmission

We use here a modified version of a well known theorem 5, 6.

Theorem 1 If every pure product state \( \otimes_{i=1}^{k} |\Psi_i^{(n)} \rangle \)
from a space \( S = \otimes_{i=1}^{k} |\Psi_i^{(n)} \rangle \) have pure–state fidelity
\( F_e(S, \mathcal{E}) > 1 - \eta \) then any density operator \( \varrho = \otimes_{i=1}^{k} |\rho_i^{(n)} \rangle \rangle, \) such that \( \text{Ran}(\varrho_l^{(n)}) \subseteq S_l^n \), has entanglement fidelity
\( F_e(\varrho, \mathcal{E}) \geq 1 - O(\eta) \).

Proof of the theorem (see 5) uses two main ideas (i) not only vector from the bases have pure–state fidelity high
but arbitrary superpositions of them also, and (ii) pure–state fidelity averaged over phases is high if pure–state
fidelity is high. (Note that we consider here global fidelities which in virtue of lemmas from section IIIC are
equivalent to local ones in context of capacities). To recognize usefulness of the theorem take uniform density
matrices on each \( l \)-th subspace \( H_l^{(n)} \), i.e. \( I_l^{(n)}/\dim H_l^{(n)} \). We conclude from the theorem that this source can be
sent reliably which means that all rates for entanglement transmission not less than for that of subspace transmission
are achievable.

We obtained two opposite inequalities for rates of transmission which means equality of capacities.

IV. ENCODINGS

A. Sufficiency of isometric encodings

As one knows isometric encodings is sufficient to achieve SUC capacity 5. We show that it is true for
all classes of quantum channels considered in the paper (SUC, MAC, km–UC). Bearing in mind that the protocol
is agreed before sending any information through the channel so that both encoding and decoding depend
on the source we will construct explicitly isometry which will serve as an encoding. We start with recalling theo-
rem about sufficiency of isometric encodings in case of a single user channel as its proper application will be a
main tool in proving the upcoming central theorem of the section. We have

Lemma 3 5 Given a trace–non-increasing map \( \mathcal{A} \)
and a map \( \varepsilon \) trace–preserving on the state \( \mathcal{B} \equiv \text{tr}_A \Psi_{AB}, \) for which
\( F_e(\Psi_{AB}, \mathcal{A} \circ \varepsilon) > 1 - \eta \), one can always find such
partial isometry \( W \) that \( F_e(\Psi_{AB}, \mathcal{A} \circ \varepsilon, W) > 1 - 2\eta \).

To apply the above we take \( \mathcal{A} = D \circ \Lambda, \) i.e. concatenation of channel noise and decoding.

Central point of this section is a theorem

Theorem 2 Given a reliable protocol \( P^C = \{ D^{(n)}, \varepsilon^{(n)} \}, \)
\( \varepsilon^{(n)} = \otimes_{i=1}^{k} \varepsilon_{i}^{(n)} \), there always exists an extendable to a
trace–preserving map partial isometry \( W^{(n)} = \otimes_{i=1}^{k} W_{i}^{(n)} \)
such that a protocol \( P^C = \{ D^{(n)}, W^{(n)} \} \) allows for rel-
iable entanglement transmission with the same rate.

Proof: For clarity we omit a superscript “(n)” in the proof. Using shorthand notation for \( \mathcal{A} \) as previously (the
difference is that in the setting considered now we have \( m \)-fold tensor product of decodings) reliable entan-
glement transmission condition in multiparty scenario takes the form

\[
F_e(\otimes_{i=1}^{k} \Psi_{(AB)_i}, \mathcal{A} \circ \otimes_{i=1}^{k} \varepsilon_{i}) > 1 - \eta.
\]

(22)
Assume now $A$ and $\varepsilon_i$-s have Kraus representations as follows

$$A(\cdot) = \sum_\alpha A_\alpha(\cdot)A_\alpha^\dagger, \quad (23)$$

$$\varepsilon_i(\cdot) = \sum_\beta E_\beta^\varepsilon_i(\cdot)E_\beta^\varepsilon_i, \quad (24)$$

One verifies that independently of what purifications $\Psi_{(AB)}$, we choose we have

$$F_c\left(\otimes_{i=1}^k \Psi_{(AB)}\right) = A \circ \otimes_{i=1}^k \varepsilon_i,$$

$$= \sum_\beta \sum_{\beta_1, \beta_2, \cdots, \beta_k} \sum_{\gamma_1 \gamma_2 \cdots \gamma_k} \sum_{\alpha} \left(\langle \phi_{B_i}^{\beta_i} | \phi_{B_i}^{\beta_i} \rangle \right) A_\alpha \otimes_{i=1}^k \left( E_{\beta_i}^{\varepsilon_i} | \phi_{B_i}^{\beta_i} \rangle \right)^2,$$

where $\phi$-s come from spectral decompositions of $\varrho$-s, i.e.

$$\varrho_{B_i} = \sum_\gamma \gamma_i | \phi_{B_i}^{\gamma_i} \rangle \langle \phi_{B_i}^{\gamma_i} | \equiv \sum_\gamma | \phi_{B_i}^{\gamma_i} \rangle \langle \phi_{B_i}^{\gamma_i} |.$$  

Now let us define some operators by partial inner product

$$A_{\alpha, \beta_1, \beta_2, \cdots, \beta_k}^{(1)} \equiv \sum_{\gamma_1 \gamma_2 \cdots \gamma_k} \sum_\gamma \sum_\alpha \left( \langle \phi_{B_i}^{\gamma_i} | \phi_{B_i}^{\gamma_i} \rangle \right) A_\alpha \otimes_{i=1}^k \left( E_{\beta_i}^{\varepsilon_i} | \phi_{B_i}^{\gamma_i} \rangle \right)^2,$$

This allows us to rewrite as

$$F_c\left(\otimes_{i=1}^k \Psi_{(AB)}\right) = A \circ \otimes_{i=1}^k \varepsilon_i,$$

$$= \sum_\beta \sum_{\alpha} \left( \sum_{\gamma_1 \gamma_2 \cdots \gamma_k} \sum_\gamma \sum_\alpha \langle \phi_{B_i}^{\gamma_i} | \phi_{B_i}^{\gamma_i} \rangle \right) A_\alpha \otimes_{i=1}^k \left( E_{\beta_i}^{\varepsilon_i} | \phi_{B_i}^{\gamma_i} \rangle \right)^2,$$

with some channel $A_1$ defined by its Kraus decomposition

$$A_1(\cdot) = \sum_{\theta, \kappa_1 \kappa_2 \cdots \kappa_k} A_{\theta, \kappa_1 \kappa_2 \cdots \kappa_k}^{(1)}(\cdot) A_{\theta, \kappa_1 \kappa_2 \cdots \kappa_k}^{(1)}.$$  

The above due to $\Psi_{(AB)}$-s is still high and by the Lemma 3 we can find such $W_1$ that

$$F_c(\Psi_{(AB)}), A_1 \circ W_1 > 1 - 2\eta.$$  

Now bearing in mind $= \Psi_{(AB)}$, we conclude that the latter can be written as

$$F_c\left(\otimes_{i=1}^k \Psi_{(AB)}\right), A \circ W_1 \otimes \left( \otimes_{i=1}^k \varepsilon_i \right) > 1 - 2\eta.$$  

This proofs the existence of partial isometries as good encodings. This with the aid of the fact that we still use the same source concludes the proof.  

In general the isometry can be trace–decreasing, however, as pointed in $\Psi$ it can be embedded in trace–preserving map without loss of fidelity. This make it useful as an proper encoding.

### B. Entanglement capacities without encodings: MAC and k–UC

The authors of $\Psi$ have shown that introducing encoding to the coding scheme is not necessary to get the proper definition of channel capacity for entanglement transmission of SUC. We show that with additional constraint it is also the case for MAC and k-UC (in the setting one sender–one receiver). One must stress that we prove it for entanglement transmission without assuming QAEAP property of the sources.

The idea is to show that we can get rid of encodings on the Alicias' side if Bobbys perform an additional decoding operation. Here is the motivation (we shall operate on the definition of capacity for entanglement transmission). Suppose $\left( \otimes_{i=1}^k \varrho_{B_i}^{(n)} \right)$ is a purification of $\left( \otimes_{i=1}^k \varrho_{B_i}^{(n)} \right)$ which Alicias are supplied with. Performing encoding by them means adjoining environment in a standard state and unitary acting on the composed system.  

As the environments are just an additional subsystems which are not sent over the channel they can measure them. This results with some probability (dependent on the result of the measurement) in different pure states $\left( \otimes_{i=1}^k \psi_{B_i}^{(n)} \right)$ on Alicias side. However each Alicia have access only to a part of a resulting state, the other is a reference system which we assume to be out of control of any parties taking part in communication. The aim is to show that if they use $\left( \otimes_{i=1}^k \psi_{B_i}^{(n)} \right)$ as an input they can also achieve high entanglement fidelity as it was for original $\left( \otimes_{i=1}^k \varrho_{B_i}^{(n)} \right)$ if additional (local) operation will be performed on Bobbys’ side. It will remain to show that entropy rate of a new source is close to that of the old one.

We start with the lemmas.

**Lemma 4** $\Psi$ If $\langle \phi_1 | \psi_1 \rangle^2 > 1 - \eta_1$ and $\langle \phi_2 | \psi_2 \rangle^2 > 1 - \eta_2$ then $\langle \phi_1 | \psi_2 \rangle^2 > 1 - \eta_1 - \eta_2$ for normalized $\phi$.

**Lemma 5** $\Psi$ Given a density matrix satisfying

$$\langle \phi_1 | \phi_1 \rangle > 1 - \epsilon$$  

for some state $\phi$ we have (i)

$$\lambda_{\text{max}} > 1 - \epsilon$$  

and (ii)

$$\langle \psi_{\text{max}} | \phi \rangle^2 > 1 - 2\epsilon$$
where $\lambda_{\text{max}}, \psi_{\text{max}}$ are the largest eigenvalue and corresponding eigenstate respectively.

The central element of the technique to prove the upcoming Theorem is the subsequent Lemma 7 which is a subtle generalization of the corresponding lemma from §.

**Lemma 6** Given a density matrix $\varrho$ in Hilbert space $\mathcal{H}_{\text{AB}} = \otimes_{i=1}^{k} \mathcal{H}_{(\text{AB}_i)}$, $\mathcal{H}_{\text{AB}} = \mathcal{H}_A \otimes \mathcal{H}_B$, satisfying a condition $(\otimes_{i=1}^{k} |\phi_i\rangle \langle \phi_i|) > 1 - \epsilon$ there exists a purification $|\Psi\rangle = \otimes_{i=1}^{k} |\Psi_i\rangle$ of $\otimes_{i=1}^{k} \rho_i = \otimes_{i=1}^{k} \text{Tr}_{\text{AB}} \varrho_{\text{AB}}$ into Hilbert space $\mathcal{H}_{\text{ABC}} = \otimes_{i=1}^{k} \mathcal{H}_{(\text{ABC}_i)}, \mathcal{H}_{(\text{ABC})} = \mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}_C$, such that

$$\langle \Psi \mid (\otimes_{i=1}^{k} |\phi_i\rangle \langle \phi_i|) \mid \Psi \rangle > 1 - O(\epsilon),$$

where we can take $O(\epsilon) = (2k + 4)\epsilon$.

**Proof:** We can write

$$\varrho \otimes (\otimes_{i=1}^{k} 0^{C_i}) = \lambda_{\text{max}} |\phi_{\text{max}}\rangle \langle \phi_{\text{max}}| \otimes (\otimes_{i=1}^{k} 0^{C_i}) + (1 - \lambda_{\text{max}}) \varrho' \otimes (\otimes_{i=1}^{k} 0^{C_i})$$

with $\lambda_{\text{max}}$ largest eigenvalue of $\varrho$ and $|\phi_{\text{max}}\rangle$ corresponding eigenvector, and take purifications in the form

$$|\Psi_i\rangle = \sqrt{\lambda_{\text{max}}^{(i)} |\phi_{\text{max}}^{(i)}\rangle \langle \phi_{\text{max}}^{(i)}|} \otimes |0^{C_i}\rangle$$

$$+ \sqrt{1 - \lambda_{\text{max}}^{(i)}} \sum_{k=1}^{\dim \mathcal{H}_A} \sqrt{\mu_k} |\phi_k^{(i)}\rangle \otimes |k^{C_i}\rangle$$

Now

$$\langle \Psi \mid (\varrho \otimes (\otimes_{i=1}^{k} 0^{C_i})) \mid \Psi \rangle =$$

$$= (\otimes_{i=1}^{k} |\Psi_i\rangle \varrho \otimes (\otimes_{i=1}^{k} 0^{C_i})) (\otimes_{i=1}^{k} |\Psi_i\rangle) =$$

$$= \lambda_{\text{max}} (\otimes_{i=1}^{k} |\Psi_i\rangle |\phi_{\text{max}}\rangle \otimes (\otimes_{i=1}^{k} 0^{C_i}) |\phi_{\text{max}}\rangle)^2 =$$

$$= \lambda_{\text{max}} \Pi_k^{(i)} \lambda_{\text{max}} (\otimes_{i=1}^{k} |\phi_{\text{max}}^{(i)}\rangle |\phi_{\text{max}}^{(i)}\rangle)^2 \geq$$

$$\geq 1 - O(\epsilon).$$

which concludes the proof. The inequality follows from lemmas 1 and 6.

The preceding lemma is crucial for proving the main theorem of this section which is the following.

**Theorem 3** For a given reliable protocol $P = \{\mathcal{D}^{(n)}, \otimes_{i=1}^{k} \mathcal{E}^{(n)}\}$ for MAC and $k$–UC there always exists a reliable protocol $\hat{P} = \{\otimes_{i=1}^{k} \hat{\mathcal{D}}^{(n)} \otimes_{i=1}^{k} \mathcal{H}^{(n)}\}$ allowing for entanglement transmission with the same rate.

**Proof:** Assuming reliable transmission and taking $\otimes_{i=1}^{k} |\Psi^{(n)}\rangle$ purifying $\otimes_{i=1}^{k} \text{Tr}_{\text{AB}} \varrho_{\text{AB}}$ we have by Lemma 7

$$\langle \Psi^{(n)} \mid \varrho_{\text{AB}}^{\text{out}(n)} \otimes (\otimes_{i=1}^{k} 0^{C_i}) \mid \Psi^{(n)} \rangle > 1 - O(\epsilon),$$

where $\varrho_{\text{AB}}^{\text{out}(n)}$ is the density matrix after performing protocol. One can see that

$$|\Psi^{(n)}\rangle = \mathbb{I}_A \otimes (\otimes_{i=1}^{k} U^{(BC_i)}) |\psi_0^{(n)}\rangle \equiv U |\psi_0^{(n)}\rangle,$$

where $|\psi_0^{(n)}\rangle \equiv (\otimes_{i=1}^{k} |\psi_0^{(n)}\rangle \otimes (\otimes_{i=1}^{k} 0^{C_i}))$ and $U$ is unitary, as both $|\Psi^{(n)}\rangle$ and $|\psi_0^{(n)}\rangle$ are purifications of the same state. We get

$$\langle \psi_0^{(n)} \mid U \varrho_{\text{out}(n)} U^\dagger \mid \psi_0^{(n)} \rangle \geq 1 - O(\epsilon),$$

with substitution $\varrho_{\text{out}(n)} = \varrho_{\text{AB}}^{\text{out}(n)} \otimes (\otimes_{i=1}^{k} 0^{C_i})$. We see that if we add remaining terms with environment in other states to get the full trace we obtain

$$\langle \otimes_{i=1}^{k} (|\psi_0^{(n)}\rangle) \mid \text{tr} \mathcal{U} \varrho_{\text{out}(n)} U^\dagger (\otimes_{i=1}^{k} |\psi_0^{(n)}\rangle) \rangle \geq 1 - O(\epsilon).$$

(43)

So replacing input $\left(\otimes_{i=1}^{k} |\psi_0^{(n)}\rangle\right)$ with $\left(\otimes_{i=1}^{k} |\psi_i^{(n)}\rangle\right)$ and adding additional decoding operation $\hat{D}$ – appending $k$ environments, rotating the whole state locally and tracing out environments – allowed us to transmit a given source reliably. Structure of an additional operation is essential here. One can see from (43) that it must be alike coding operation. This is what makes the technique used above useful only in the case of $k$–UC (in the setting one sender–one receiver) and MAC. It is interesting that although Bobby can perform in case of MAC global decoding it suffices to perform local operations to achieve reliable transmission. Previous considerations fail in case of general broadcast channel (only in the case of broadcast channels for which product coding suffices we can apply our theorem). To conclude the proof it remains to show that entropy of new sources producing $\varrho^{(n)} \equiv \text{tr} A (\otimes_{i=1}^{k} |\psi_i^{(n)}\rangle)$ is close to the old one producing $\varrho^{(n)} \equiv \text{tr} A (\otimes_{i=1}^{k} |\phi_i^{(n)}\rangle)$. Following lemma, which is a simple generalization of lemma from §, will be deciding.

**Lemma 7** For a given pure state $|\phi\rangle \equiv \otimes_{i=1}^{k} |\phi_i\rangle$ and density matrix $\varrho$ in Hilbert space $\mathcal{H} = \otimes_{i=1}^{k} \mathcal{H}_{(\text{AB}_i)}$, with $\langle \phi \mid \varrho \mid \phi \rangle \geq 1 - \epsilon$ and $\epsilon < \frac{1}{12}$ we have

$$|S(\text{tr} A \varrho) - S(\text{tr} A \varrho)| \leq 2 \sqrt{2} \epsilon \log \dim \mathcal{H}_{B} + 2.$$ (44)

We have by the lemma and high entanglement fidelity assumption for $\left(\otimes_{i=1}^{k} |\phi_i^{(n)}\rangle\right)$

$$|S(\text{tr} B \otimes_{i=1}^{k} |\phi_i^{(n)}\rangle) - S(\text{tr} B \otimes_{i=1}^{k} \varrho_{\text{AB}}^{\text{out}(n)})| \leq$$

$$\leq 2 \sqrt{2} \epsilon \log \dim \mathcal{H}_{A} + 2$$

for $\epsilon < \frac{1}{12}$. Following equalities hold

$$\text{tr} B \otimes_{i=1}^{k} \varrho_{\text{AB}}^{\text{out}(n)} \equiv \text{tr} B \left(\otimes_{i=1}^{k} |\psi_i^{(n)}\rangle\right), S \left(\text{tr} B \left(\otimes_{i=1}^{k} |\psi_i^{(n)}\rangle\right)\right) =$$

$$S \left(\text{tr} A \left(\otimes_{i=1}^{k} |\psi_i^{(n)}\rangle\right)\right) \equiv S(\varrho^{(n)}), S \left(\text{tr} B \left(\otimes_{i=1}^{k} |\phi_i^{(n)}\rangle\right)\right) =$$

$$S \left(\text{tr} A \left(\otimes_{i=1}^{k} |\phi_i^{(n)}\rangle\right)\right) \equiv S(\varrho^{(n)})$$

which immediately implies

$$|S(\varrho^{(n)}) - S(\varrho^{(n)})| \leq 2 \sqrt{2} \epsilon \log \dim \mathcal{H}_{A} + 2.$$ (46)

The latter means that in the limit of large $n$ we achieve the same transmission rate for the new source. The above
reasoning holds for each “subtransmission”, i.e. each local entropy, which means that information is localized without changes.

However, we must stress again we are not able to show that new source is QAEP if the original one was. Most probably it is not possible in general, i.e. encodings is necessary to preserve QAEP (besides the trivial case when input density matrix is almost maximally chaotic on channel input space).

V. FORWARD CLASSICAL COMMUNICATION DOES NOT IMPROVE CAPACITY REGIONS

Now we turn to the case when quantum transmission is supplemented by classical noiseless forward channel. It is well known fact that classical support does not increase capacity of SUC. We show this is the case for all quantum channels considered in the paper. Our strategy will be to construct a reliable zero–way protocol from reliable one–way protocol without changing the rate which shows uselessness of classical communication does not help. This was achieved by changing the rate which shows uselessness of classical communication does not help. This was achieved by using the result proves optimality of recently derived by other authors zero–way capacity regions also for one–way scenario. We have also considered multiple access channel and k–user channel separately and shown that entanglement transmission capacity can be achieved also without encoding. This result however does not seem to be true for broadcast channel and in cases when one assumes QAEP sources.

The results of the present paper can be applied to get simple capacity regions for quantum broadcast and k–user channels, but this will be considered elsewhere [24].

VII. APPENDIX

A. Quantum Asymptotic Equipartition Property (QAEP)

Here we recall definitions for quantum analogs of typical subspace and equipartition property. Classical formulas are easily adopted to the quantum case and one has the following

Definition 1 We define ε– typical subspace of a n–block ρ(n) produced by a quantum source Σ on a Hilbert space H to be the subspace Tε(Σ) of H(n) spanned by the eigenvectors |λ⟩ of ρ(n) with eigenvalues λ satisfying

$$2^{-n(H(Σ)+ε)} ≤ \lambda ≤ 2^{-n(H(Σ)-ε)}$$

(47)

Definition 2 We say a quantum source Σ producing n–block material ρ(n) satisfies QAEP iff for any positive ε and δ in the limit of large n the ε–typical subspace of ρ(n) satisfies

$$\text{tr} \Lambda(n)\delta(n)\Lambda(n) > 1 - δ$$

(48)

where Λ(n) denotes the projection onto Tε(Σ).

We can think about ε–typical subspace as a small set containing almost all probability. Obviously a tensor product of QAEP sources is also QAEP.

B. Proof of Eq. (21)

Consider the global entanglement fidelity F_e$$\left(\otimes_{i=1}^{k} \otimes_{\alpha=1}^{l} |\Psi_i^{(\alpha)}⟩\right), A(n)$$ ≥ 1 − η with η = \varepsilon L_i. By convexity of entanglement fidelity in the input operator we have the following

$$1 - η ≤ (1 - η)\Pi_{i=1}^{L} α_i + \Pi_{i=1}^{L} (1 - α_i),$$

(49)
where $\gamma$ describes imperfection of global pure state transmission of vectors from the subspace after having removed dimensions (i.e. $F_s \geq 1 - \gamma$). One can verify that

$$\Pi_{l=1}^{L} \alpha_l + \Pi_{l=1}^{L} (1 - \alpha_l) \leq 1 \quad (50)$$

as for $k$ it is trivially true and multiplying of each component just lowers the number. With the aid of the above and results of IID we immediately conclude the bound for local pure–state fidelity

$$F_s^{(l)} \geq 1 - \frac{\sum_{l=1}^{L} \eta_l}{\Pi_{l=1}^{L} \alpha_l} \quad (51)$$

[27] We slightly modify the previous definition that involves limes supremum. This does not change the final rate.
[28] This is a multiparty generalization of the formula (11) of
